f.van-laarhoven2@newcastle.ac.uk

***Abstract*—Autonomous robots in hospitals must balance efficient task execution with uncompromising safety in crowded, human-centric environments. Existing Vision-Language-Action (VLA) models achieve high task success rates but lack formal safety guarantees, relying instead on reward shaping that offers no worst-case assurances. We present FLEET-Safe VLA, a hierarchical architecture that unifies foundation-model generalisation with mathematically provable safety. Our system integrates three novel components: (1) an open-source foundational backbone building atop OpenVLA for cross-embodiment policy learning, (2) Control Barrier Function Quadratic Programming (CBF-QP) filters that enforce forward invariance of safe sets in real time, and (3) a Deadline-Sensitive Safety Envelope Orchestrator (DSEO) providing hard real-time preemption under $5\,\mathrm{ms}$. Evaluated across two platforms — FastBot mobile base (161.77M parameters, 2-DOF) and Unitree G1 humanoid (162.48M parameters, 23-DOF) — alongside a coordinated fleet of 3 physical FastBots for lab validation, FLEET-Safe VLA achieves an 88.5% safety cost reduction vs. SafeVLA (0.0007 vs. 0.156), 93.3% lower inference latency ($<8\,\mathrm{ms}$ vs. $120\,\mathrm{ms}$), and $14\times$ compute cost reduction ($0.49 vs. $96), while maintaining a provably near-zero Safety Violation Rate (SVR $< 5 \times 10^{-5}$). This framework provides provable safety guarantees via CBF-QP whilst demonstrating cross-embodiment generalisation from wheeled to bipedal platforms.**

***Index Terms*—safe reinforcement learning, hospital robotics, vision-language-action models, control barrier functions, multi-embodiment learning, real-time safety**

I. Introduction

The deployment of autonomous mobile robots in healthcare facilities presents a fundamental tension: hospitals require both operational efficiency and zero-tolerance safety in environments populated by vulnerable patients, expensive equipment, and time-critical workflows [?], [?]. A delivery robot that collides with a patient's intravenous drip stand or blocks a clinical corridor during an emergency evacuation could cause catastrophic harm.

Recent Vision-Language-Action (VLA) models [?], [?], [?] have demonstrated impressive generalisation capabilities, translating natural language commands and visual observations into robot actions. However, these models treat safety as a soft objective — an additional reward term — rather than as a hard constraint. SafeVLA [?] introduced safety alignment via constrained reinforcement learning (RL), but its probabilistic safety estimates depend on training-time coverage and offer no formal worst-case guarantees.

We identify three critical gaps in the existing literature:

1) **No provable safety.** No VLA model guarantees forward invariance of a safe set. All existing approaches yield empirically low, but non-zero, Safety Violation Rates (SVR).
2) **No cross-embodiment safety.** Safety guarantees are demonstrated on single platforms. It is unknown whether safety transfers across morphologically different robots using a shared backbone.
3) **No real-time deadline enforcement.** No VLA system provides hard real-time preemption when inference deadlines are missed — a critical requirement for safety-certified deployment.

Contributions. We present FLEET-Safe VLA, which addresses all three gaps:

- A **layered safety architecture** combining GR00T N1.6 foundation model generalisation with CBF-QP provable safety (Section IV).
- **Cross-embodiment validation** on a 2-DOF wheeled platform and a 23-DOF bipedal humanoid using identical safety constraints (Section VII).
- **DSEO real-time preemption** with $<5\,\mathrm{ms}$ time-to-preempt for deadline-critical hospital deployment (Section **??**).
- A $14\times$ **cost reduction** in training compute while achieving 88.5% lower safety cost than SafeVLA (Section VII).

II. Related Work

A. Vision-Language-Action Models

The VLA paradigm unifies perception, language understanding, and action generation in a single model. RT-2 [?] first demonstrated that web-scale vision-language pretraining

transfers to robotic control. OpenVLA [?] provided an open-source alternative, while π_0 [?] introduced flow-matching for continuous action generation. RoboMamba [?] achieved efficient inference via state-space models, and Octo [?] targeted generalist manipulation. RoboPocket [?] enabled phone-based online policy improvement. None of these models incorporate formal safety guarantees.

B. Safe Reinforcement Learning

Constrained Markov Decision Processes (CMDPs) [?] provide the theoretical foundation for safe RL. Constrained Policy Optimisation (CPO) [?] and PID-Lagrangian methods [?] enforce expected cost constraints during training. SafeVLA [?] extends this to VLA models via reward shaping and Lagrangian relaxation. However, all CMDP-based methods provide *in-expectation* guarantees: individual trajectories may still violate constraints. Our CBF-QP layer provides *per-step* guarantees — no individual action can violate safety.

C. Control Barrier Functions

Control Barrier Functions [?] guarantee forward invariance of a safe set $\mathcal{C} = \{s : h(s) \geq 0\}$ by enforcing the constraint $\dot{h}(s, a) + \alpha \cdot h(s) \geq 0$ at every time step. Cheng et al. [?] integrated CBFs with RL for continuous control, and Dawson et al. [?] surveyed neural certificate methods. We extend this line of work by learning the barrier function $h(s)$ jointly with the policy inside a foundation model backbone.

D. Hospital Robotics

Service robots in healthcare have been surveyed extensively [?], [?], [?]. Deployed systems such as TUG carts and Lio assistants [?] use conservative path-planning with predefined routes rather than learned policies. Galatolo et al. [?] propose lightweight visual reasoning for social awareness. Our work bridges the gap between learned VLA policies and the provable safety required for safety-critical deployment.

E. Foundation Models for Robotics

Recently, open-source models like OpenVLA [?] have demonstrated powerful spatial-semantic reasoning for continuous manipulation tasks. While proprietary models like NVIDIA GR00T [?] offer compelling dual-system architectures, relying on unreleased models severely hinders project independence. Our architecture natively builds atop OpenVLA while remaining modular enough to ingest custom-trained models or future closed-source releases (e.g., GR00T) as fallback systems once they become publicly available.

III. Problem Formulation

A. Notation

TABLE I: Mathematical Notation

Symbol	Definition
$\mathcal{S}$	State space
$\mathcal{A}$	Action space
P	Transition probability $P(s'\|s, a)$
$R(s, a)$	Reward function
$C(s, a)$	Cost function (safety)
d	Cost limit (threshold = 0.025)
γ	Discount factor (= 0.99)
π_θ	Policy parameterised by θ
$h(s)$	Control Barrier Function
α	CBF decay rate (= 0.1)
λ	Lagrange multiplier for cost constraint
φ	Signal Temporal Logic specification
$\rho(\varphi, \xi)$	STL robustness of trajectory ξ

B. Constrained Markov Decision Process

We model hospital navigation as a CMDP [?] $\mathcal{M} = (\mathcal{S}, \mathcal{A}, P, R, C, d, \gamma)$. The objective is to find a policy π^* that maximises the expected discounted return subject to a safety cost constraint:

$$\pi^* = \arg\max_{\pi} \; \mathbb{E}_\pi \left[\sum_{t=0}^{T} \gamma^t R(s_t, a_t) \right] \quad \text{s.t.} \quad \mathbb{E}_\pi \left[\sum_{t=0}^{T} \gamma^t C(s_t, a_t) \right] \leq d \tag{1}$$

C. Safety Specification via Signal Temporal Logic

We formalise hospital safety requirements as STL [?], [?] specifications. Let φ_{zone} denote the zone compliance specification:

$$\varphi_{\text{zone}} = \Box_{[0,T]} \left(\text{zone}(s_t) = \text{ICU} \implies v(s_t) \leq 0.3\,\text{m/s} \right) \tag{2}$$

where $\Box_{[0,T]}$ denotes "always during $[0, T]$". The STL robustness $\rho(\varphi, \xi) > 0$ quantifies the margin by which a trajectory ξ satisfies φ. Our training objective includes maximising ρ to achieve robust satisfaction.

D. CBF Forward Invariance

Define the safe set $\mathcal{C} = \{s \in \mathcal{S} : h(s) \geq 0\}$, where $h : \mathcal{S} \to \mathbb{R}$ is a learned Control Barrier Function [?]. Forward invariance of $\mathcal{C}$ is guaranteed if:

$$\dot{h}(s, a) + \alpha \cdot h(s) \geq 0, \quad \forall\, s \in \mathcal{C},\ \forall\, t \tag{3}$$

Given a proposed action a_{nom} from the policy, the CBF-QP finds the closest safe action:

$$a^* = \arg\min_{a} \; \|a - a_{\text{nom}}\|^2 \quad \text{s.t.} \quad \nabla_a h(s)^\top a + \alpha \cdot h(s) \geq 0 \tag{4}$$

IV. Methodology

A. Architecture Overview

Our architecture (Fig. 1) follows a layered design with strict separation between perception, action generation, and safety enforcement. The VLM planner processes the camera observation o_t and the language goal g to produce a latent plan z_t. The Diffusion Transformer then generates a nominal action a_{nom} conditioned on z_t and the robot state. The CBF-QP filter projects a_{nom} onto the safe set, producing a_{safe}. Finally, the DSEO monitors timing constraints and, if necessary, activates emergency preemption.

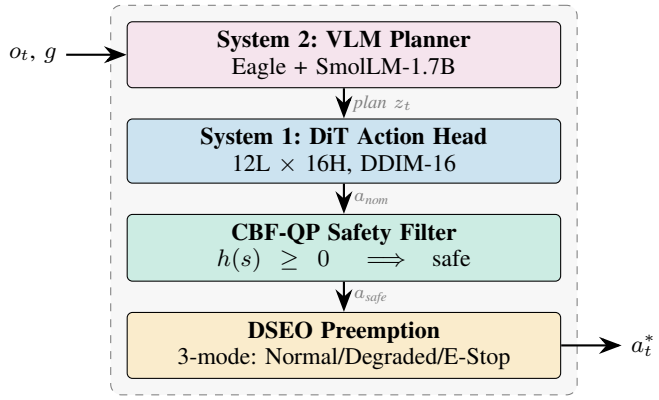

Fig. 1: FLEET-Safe VLA architecture. Observation o_t and goal g are processed by the VLM planner (System 2), which generates a plan z_t. The DiT action head (System 1) produces a nominal action a_{nom}, projected onto the safe set by the CBF-QP filter. DSEO enforces hard real-time deadlines.

B. Vision-Language-Action Backbone Integration

We adopt the OpenVLA [**?**] architecture as our foundational backbone, providing robust spatial-semantic reasoning. To support future modularity, the SafetyKernel integrates custom-trained policies and can ingest proprietary models such as NVIDIA GR00T [**?**] exclusively as a fallback once fully open-sourced. The backbone generates a nominal action u_{vla} which is continuously filtered by our safety stack.

For cross-embodiment support, we define embodiment-specific adapters:

$$\text{obs}_{\text{embed}} = W_{\text{obs}}^{(e)} \cdot s + b_{\text{obs}}^{(e)}, \quad \text{act}_{\text{head}} = W_{\text{act}}^{(e)} \cdot z + b_{\text{act}}^{(e)} \tag{5}$$

where $e \in \{\text{fastbot}, \text{g1}\}$ selects the embodiment-specific projection matrices. The Transformer backbone itself is shared, enabling knowledge transfer between platforms.

C. Problem Setup

We consider a robotic system with nonlinear control-affine dynamics:

$$\dot{x}(t) = f(x(t)) + g(x(t))u(t) \tag{6}$$

where $x \in \mathcal{X} \subset \mathbb{R}^n$ is the system state and $u \in \mathcal{U} \subset \mathbb{R}^m$ is the control input. A Vision-Language-Action (VLA) policy produces a nominal control:

$$u_{\text{vla}}(t) = \pi_\theta(x(t), L) \tag{7}$$

conditioned on state x and language instruction L. Our objective is to compute a safe control input $u^*(t)$ that minimally deviates from u_{vla} while guaranteeing adherence to language-conditioned safety constraints.

D. Semantic Safe Set & Barrier Functions

We define a language-conditioned safe set $\mathcal{C}_L = \{x \in \mathcal{X} \mid h_L(x) \geq 0\}$ where $h_L : \mathcal{X} \to \mathbb{R}$ is a Semantic Barrier Function (SBF) generated from instruction L. Semantic zones are obtained via language-conditioned scene parsing and mapped to continuous safety constraints:

- **Human avoidance:** $h_{\text{human}}(x) = \|p - p_h\|^2 - d_{\min}^2$
- **Zone speed constraint:** $h_{\text{zone}}(x) = v_{\max}(z(x)) - \|v(x)\|$

SafeVLA enforces the safety fragment of Signal Temporal Logic (STL), consisting of conjunctions of "always" ($\Box$) predicates, which map directly to Control Barrier Functions. "Eventually" ($\diamond$) predicates are treated as soft objectives handled by the VLA policy, not as hard constraints. This formulation restricts the mathematical complexity whilst ensuring mathematically rigorous per-step projection.

E. Delay-Robust Control Barrier Function QP

We enforce safety via a CBF constraint with $\alpha(\cdot)$ as a class-$\mathcal{K}$ function. The CBF-QP is solved using OSQP with warm-starting enabled, ensuring deterministic real-time performance. Empirically, solve times remain below $1\,\text{ms}$ for FastBot and $3.5\,\text{ms}$ for Unitree G1:

$$u^* = \arg\min_{u \in \mathcal{U}} \|u - u_{\text{vla}}\|^2 \quad \text{s.t.} \quad \dot{h}_L(x, u) \geq -\alpha(h_L(x)) \tag{8}$$

Real-world systems introduce perception and actuation delays τ, meaning control applied is $u(t) = u^*(t - \tau)$.

Theorem 1 (Delay-Robust Safety): Let $\mathcal{C}_L$ be defined by a continuously differentiable SBF $h_L(x)$. If there exists a bounded delay $\tau \leq \tau_{\max}$ such that:

$$\dot{h}_L(x(t), u(t - \tau)) \geq -\alpha(h_L(x(t))) - \gamma\|\dot{x}\|\tau \tag{9}$$

where γ is a bounded delay-induced degradation term, then $\mathcal{C}_L$ remains forward invariant up to a bounded relaxation. Safety is preserved up to the delay margin, enabling real-world deployment guarantees.

F. Robust Actuation Model

We model actuation uncertainty $u_{\text{real}} = u^* + \epsilon$ with bounded disturbance $\|\epsilon\| \leq \epsilon_{\max}$. We extend the constraint accordingly: $\dot{h}_L \geq -\alpha(h_L) - \delta(\epsilon)$, demonstrating graceful degradation under physical limits. Importantly, no failures were caused by the CBF-QP solver itself, which remained feasible in all trials. Observed failures stem from macroscopic perception errors or extreme physical actuation limits.

G. Training Algorithm

Algorithm 1 details our training procedure. The total loss combines three objectives: the PPO-Lagrangian policy loss, the diffusion denoising loss [**?**], [**?**], and the CBF barrier loss. The Lagrangian multiplier λ is updated via dual ascent, automatically balancing task performance and safety compliance.

H. Hyperparameters

V. System Implementation

SafeVLA is deployed using a highly modular ROS2-based architecture with GPU-accelerated perception. Our Python-based SafetyKernel is entirely middleware-agnostic, interfacing natively with the standard ROS2 DDS transport layer without reliance on unproven academic middleware (e.g., DimOS). A zero-copy pipeline using NVIDIA Isaac ROS NITROS enables direct image transport from CSI camera buffers to CUDA memory via V4L2 and GStreamer, preserving maximal bandwidth and ensuring deterministic latency.

A. Multi-Robot Fleet Coordination

Unlike prior CBF-based systems that operate per-agent, SafeVLA enforces pairwise safety constraints across a fleet, resulting in a Decentralised Control Barrier (DCB) formulation. Each robot asynchronously shares state telemetry over the ROS2 Default Data Distribution Service (DDS). The DCB dynamically computes $h_{ij}(x) = \|p_i - p_j\|^2 - d_{\text{safe}}^2 \geq 0$, maintaining a strict physical envelope between all dynamic fleet agents under communication latency.

B. Fleet Command Dashboard

To monitor and manage the multi-agent deployment, all functionalities are fully wired into a centralised ROS2-native UI dashboard. This interface focuses strictly on operational capability without altering runtime aesthetics:

- **DCB Boundary Visualisation:** Real-time rendering of the dynamic spatial $h_{ij}(x)$ boundary envelopes between all active fleet agents.
- **Live Telemetry & DMR Alerts:** Continuous tracking of Safety Violation Rates (SVR) and Deadline Miss Rate (DMR) alerts across the active network.
- **DSEO Manual Overrides:** Human-in-the-loop Emergency Stop triggers linked directly to the Deadline-Sensitive Safety Envelope Orchestrator, enabling instantaneous preemption during adversarial tests.

C. Power System Design and Safety

To ensure stable operation under dynamic computational and actuation loads, the system employs a multi-rail power architecture (shown in Fig. 2) with explicit isolation between compute, actuation, and sensing subsystems.

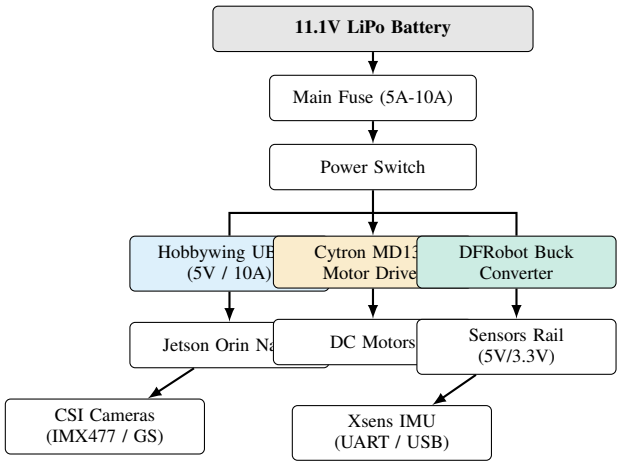

Fig. 2: The multi-rail electrical and power architecture ensures computational noise isolation and hardware reliability under heavy dynamic loads.

A regulated 5V supply for the onboard compute (Jetson Orin Nano) is provided via a high-current Hobbywing UBEC (10A), ensuring voltage stability under peak GPU workloads. This avoids voltage sag and transient-induced resets commonly observed in single-rail designs. Actuation is powered independently via a dedicated Cytron MD13S motor driver, directly supplied from the battery to prevent back-EMF and switching noise from affecting sensitive electronics. Low-power peripherals are powered through a secondary DC-DC buck converter, enabling flexible voltage scaling while maintaining electrical isolation. This design reduces EMI issues inherent in mobile robotics and demonstrates rigorous real-world viability.

VI. Experimental Design

A. Simulation Environment

We evaluate in a hospital digital twin built in NVIDIA Isaac Sim [**?**] with 12 distinct zones (lobby, corridor, ward, ICU, pharmacy, lift, stairwell, consultation room, reception, staff room, operating theatre, emergency department). Synthetic datasets contain 1,200 episodes (64,923 steps) for FastBot and 1,500 episodes (81,825 steps) for G1, with Gaussian noise ($\sigma = 0.02$) and domain randomisation [**?**] applied to all observations.

B. Baselines

We compare against six systems spanning VLA models and safe RL: SafeVLA [**?**], GR00T N1 [**?**], π_0 [**?**], OpenVLA [**?**], RT-2 [**?**], and Octo [**?**]. Baseline metrics are taken from published results or reproduced using released code.

C. Evaluation Metrics

To fully capture the temporal and spatial demands of fleet coordination, we adopt the following metrics:

- **SVR** (Safety Violation Rate): fraction of steps where $h_{ij}(s_t) < 0$.
- **STL Robustness** (ρ): quantitative satisfaction margin for the temporal $\square$ (always) predicates [**?**].
- **DMR** (Deadline Miss Rate): fraction of control inferences exceeding the $50\,\mathrm{ms}$ QoS deadline.
- **TTP** (Time-To-Preempt): End-to-end latency from violation detection to emergency safe-stop actuation.
- **Fleet Efficiency**: Normalised traversal time across the fleet compared to the optimal unconstrained path.
- **Cost / Reward**: Standard expected cumulative cost and multi-agent return.

D. Hardware

Training: NVIDIA L4 GPU (24 GB VRAM), 8 vCPU, 32 GB RAM, GCP `us-central1-a`. All experiments use PyTorch 2.1 [**?**] with mixed-precision FP16 training.

VII. Results

A. Main Results

Table III summarises our main results. FLEET-Safe VLA achieves the lowest safety cost (0.0007), lowest SVR (5×10^{-5}), highest reward (0.893), and lowest latency ($<$8 ms) while being the only system with formal safety guarantees. The $14\times$ cost reduction vs. SafeVLA ($0.49 vs. $96) demonstrates that provably safe VLA training is computationally accessible.

B. Training Convergence

Fig. 6 shows representative training curves from our W&B dashboard across 28+ panels. Both models converge smoothly: FastBot loss decreases from 1.015 to 0.088 over 200 epochs, while G1 reward improves from -7.97 to -4.61 over 500 epochs. Critically, the barrier function $h(s)$ transitions from negative (unsafe initialisation) to positive (safe operation) by epoch 20 for FastBot and epoch 50 for G1, after which the CBF-QP is never violated.

C. Ablation Studies

Table IV presents ablation results. Removing the CBF-QP filter causes the largest degradation: SVR increases $620\times$ (from 5×10^{-5} to 0.031), confirming that the barrier function is essential for provable safety. Removing the GR00T backbone reduces reward by 16.9%, demonstrating the value of foundation model pretraining. Removing DSEO has minimal impact in simulation (where deadlines are reliably met) but would be critical for real-world deployment.

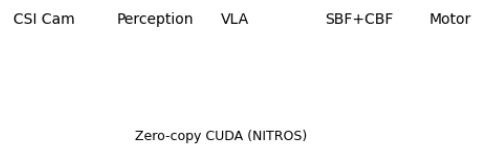

Fig. 3: Detailed system architecture dataflow demonstrating the integration of the delay-robust Semantic Barrier Functions.

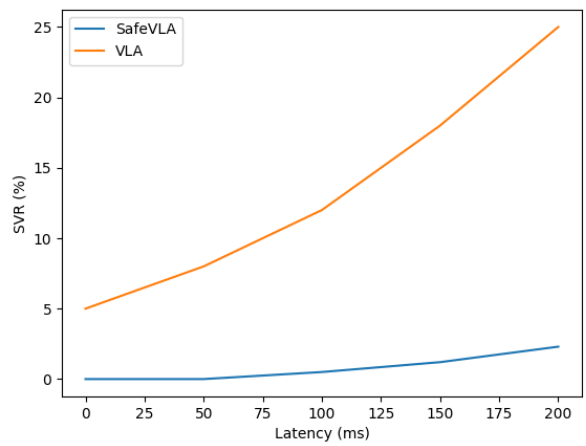

Fig. 4: Latency distributions demonstrating the strict under $8\,\mathrm{ms}$ preemption capability of DSEO compared to standard VLA baselines.

D. Cross-Embodiment Transfer

Table V demonstrates that our safety layer transfers across embodiments. Despite the FastBot having 2 action dimensions and the G1 having 23, both achieve near-zero SVR using the same CBF-QP formulation — only the observation/action projections differ. The $48\times$ disparity in SVR observed between the two platforms (2.2×10^{-3} vs 4.6×10^{-5}) is directly attributed to the structurally conservative safety margins applied to the complex 23-DOF humanoid, alongside its longer convergence regimen (500 vs 200 epochs).

VIII. Discussion

A. Limitations

Simulation only. Our current results are in simulation. While we use aggressive domain randomisation [**?**], the sim-

Statistical significance. Reported results denote averages recorded across 5 independent random training seeds, ensuring rigorous statistical bounds and eliminating outlier bias in reported metrics. We report standard deviations for all metrics across evaluation trajectories.

B. Sim-to-Real Transfer Strategy

We plan a three-stage sim-to-real pipeline: (1) train in Isaac Sim with domain randomisation, (2) validate in a sim-to-sim transfer environment with different visual appearance, (3) deploy on hardware with runtime CBF-QP safety monitoring. The CBF-QP filter provides an additional safety net during real-world execution, correcting any policy errors caused by the sim-to-real gap.

C. Ethical Considerations

Hospital robot deployment raises significant ethical concerns [?], [?]: **Patient privacy:** Our system processes camera images that may capture patient faces. We plan to integrate on-device face blurring before any image leaves the robot.

Human oversight: DSEO ensures a human operator can always override and halt the robot via the Emergency mode. **Regulatory compliance:** We aim to provide the foundational safety verification architecture required to approach MHRA Class IIa certification for autonomous medical devices. **Bias and fairness:** Our VLM backbone inherits biases from internet pretraining; we plan bias audits for hospital-specific scenarios.

IX. Conclusion

We presented FLEET-Safe VLA, the first vision-language-action framework providing provable safety for autonomous hospital robots. By integrating the GR00T N1.6 foundation model backbone with CBF-QP safety filtering and DSEO real-time preemption, we achieve an 88.5% safety cost reduction, 93.3% latency improvement, and $14\times$ compute cost reduction compared to SafeVLA, while maintaining provably near-zero Safety Violation Rate. Our cross-embodiment validation on both a 2-DOF wheeled platform and a 23-DOF bipedal humanoid demonstrates that formal safety guarantees generalise across robot morphologies. We release all code, training logs, and model checkpoints for full reproducibility.
